WEEKLY REPORT

461 Prevalence of Selected Cardiovascular Disease Risk Factors Among American Indians and Alaska Natives—United States, 1997
465 HIV/AIDS Among Men Who Have Sex With Men and Inject Drugs—United States, 1985–1998
470 Heat-Related Illnesses, Deaths, and Risk Factors—Cincinnati and Dayton, Ohio, 1999, and United States, 1979–1997

Prevalence of Selected Cardiovascular Disease Risk Factors Among American Indians and Alaska Natives — United States, 1997

Heart disease and stroke, the principal causes of cardiovascular disease (CVD), are the first and fifth leading causes of death among American Indians and Alaska Natives (AI/AN) (*1,2*). Risk factors for CVD frequently cluster, which may increase CVD risk multiplicatively (*3*). To characterize the prevalence of risk factors for CVD (i.e., hypertension, current cigarette smoking, high cholesterol, obesity, and diabetes) among AI/AN, CDC analyzed data from the 1997 Behavioral Risk Factor Surveillance System (BRFSS). This report summarizes the results of that analysis, which indicated that 63.7% of AI/AN men and 61.4% of AI/AN women who participated in the survey had one or more CVD risk factors.

BRFSS is an ongoing state-based, random-digit–dialed telephone survey of the U.S., noninstitutionalized civilian population. Self-reported data were analyzed for the 1820 AI/AN aged ≥18 years who participated in the 1997 BRFSS in 50 states and the District of Columbia (DC). Identification of race as AI/AN was based on response to the question, "What is your race?" Awareness of hypertension, high cholesterol, and diabetes was determined by the response to, "Have you even been told by a doctor or other health professional that you have (hypertension, high cholesterol, diabetes)." Current smoking status was defined as having smoked at least 100 cigarettes during one's lifetime and still smoking at the time of the survey. Self-reported data on height and weight were used to calculate body mass index (BMI). Obesity was defined as a BMI ≥30 kg/m^2. Persons defined as employed were either employed for wages or self-employed, regardless of the number of hours spent on the job. The 50 states and DC were grouped into the four geographic regions defined by the U.S. Bureau of the Census (*1*). Sample estimates were weighted by sex, age, and race to reflect the state's noninstitutionalized civilian population. To account for the complex sampling design, SUDAAN was used for data analysis (*4*).

Of the 1820 AI/AN BRFSS participants, 46.3% were women; 63.3% were aged 18–44 years, 25.6% were 45–64 years, and 11.1% were ≥65 years (mean: 42.4 years; standard deviation=16.2); 15.9% were college graduates; 60.2% were employed; and 49.8% ranked their health status as excellent or very good. The largest percentage of AI/AN participants in the BRFSS lived in the West (47.4%), followed by the South (25.9%),

Cardiovascular Disease Risk Factors — Continued

the Midwest (17.4%) and the Northeast (9.3%).*

Approximately 22% of participants reported being told by a health professional that they had hypertension (women=23.0%, men=21.0%). Thirty-one percent reported they were current smokers (men=32.8%; women=28.8%). Approximately 16% were told by a health professional that they had high cholesterol, and 7% were told they had diabetes. Awareness of high cholesterol and diabetes was higher among women (17.6% and 9.1%, respectively) than men (13.8% and 5.5%, respectively). Nearly one fourth (23.6%) of men and nearly one fifth (19.1%) of women were categorized as obese (21.5% of all AI/AN).

Among AI/AN men, 36.3% reported having none of the selected CVD risk factors, 41.4% reported having one risk factor, and 22.3% reported having ≥2 risk factors (Table 1). Among AI/AN women, 38.6% reported having no CVD risk factors, 37.7% reported having one risk factor, and 23.7% reported having ≥2 risk factors.

The prevalence of having one or more CVD risk factors increased with increasing age (Table 1). The prevalence of having ≥2 risk factors was highest among respondents aged ≥65 years. The prevalence of having ≥2 CVD risk factors varied inversely with level of education (Table 1). Approximately 25% of AI/AN men with less than a high school education reported having ≥2 CVD risk factors, compared with approximately 15% of AI/AN men who were college graduates. AI/AN women with less than a high school education were almost three times more likely to report having ≥2 risk factors than were AI/AN women who had graduated from college. The percentage of having ≥2 risk factors was almost three times higher among unemployed women than employed women.

Half of the respondents who reported their health status as fair or poor reported having ≥2 CVD risk factors (women=51.8%; men=50.0%) compared with approximately one eighth of respondents who reported their health status as excellent or very good (women=13.3%; men=13.2%) (Table 1).

The number of reported CVD risk factors varied by geographic region (Table 1). For men, the prevalence of having ≥2 risk factors was highest in the Midwest (26.1%) and lowest in the Northeast (13.8%). Less geographic variation was observed among women. The prevalence of having ≥2 risk factors was highest in the Northeast (28.0%) and lowest in the West (20.0%).

Editorial Note: The findings in this report document the prevalence of selected CVD risk factors among AI/AN by sociodemographic characteristics and are consistent with previous findings that CVD risk factors and death rates are not uniformly distributed across regions among AI/AN (*2,5*). Higher CVD death rates have been reported among AI/AN residing in the Midwest (*2*); data from this study indicate that AI/AN men residing in the Midwest were most likely to report having ≥2 CVD risk factors. Geographic variation in risk factors and death rates may reflect differences in cultural backgrounds, historical circumstances, and socioeconomic conditions. Prevalence estimates probably are influenced by sociodemographic factors (i.e., age distribution, educational attainment, employment status, and poverty), lifestyle (i.e., physical inactivity), aspects of the social environment (i.e., educational and economic opportunities), and factors affecting the health-care system (i.e., access to health care, cost, and availability of screening for diseases and risk factors). Higher prevalences of multiple CVD risk factors among AI/AN participants who were either unemployed or had completed less than a high school education corroborate the well-documented influence of low socioeconomic status on CVD risk factors.

The findings in this report are subject to at least five limitations. First, estimates of CVD risk factors are based on self-reported data and are subject to the biases associated with self-reported data. Second, these results probably underestimate the prevalence of CVD risk factors because the data are dependent on the respondent being aware of his risk factor profile. Third, data on physical inactivity, a risk factor for CVD, was not collected in the 1997 BRFSS survey. If data on physical activity levels had been included, the prevalence of CVD risk factors among AI/AN probably would have been higher. Fourth, approximately 23% of AI/AN households do not have a telephone (*6*); these findings could underestimate the prevalence of CVD risk factors among AI/AN because persons without telephones are more likely to be of lower socioeconomic status and to have higher risk for disease (*7*). Finally, BRFSS does not collect information on reservation residency or tribal affiliation. Aggregating the AI/AN participants into relatively large geographic regions may mask important differences among the tribes.

The percentages of AI/AN with multiple CVD risk factors highlight the importance of enhancing primary prevention activities among communities of AI/AN. Through CDC's Racial and Ethnic Approaches to Community Health (REACH 2010) Project (*8*), two AI/AN communities are developing effective and sustainable programs designed to eliminate racial/ethnic disparities in CVD and diabetes. Another activity is the Inter-Tribal Heart Project, a collaboration between CDC, the Indian Health Service, and three tribal communities to determine the prevalence of risk factors for heart disease and to implement community-based heart disease prevention programs (*9*). Reducing the prevalence of CVD risk factors among AI/AN requires an understanding of the diversity of cultural values and practices among AI/AN, and historical circumstances that contributed to the current socioeconomic conditions. Therefore, tribal-specific assessments of CVD risk factor profiles and CVD morbidity and mortality profiles are needed to develop culturally relevant CVD prevention programs and policies that support heart-healthy living and working conditions for AI/AN.

HIV/AIDS Among Men Who Have Sex With Men and Inject Drugs — United States, 1985–1998

Men who have sex with men and inject drugs (MSM/IDU) pose unique challenges for human immunodeficiency virus (HIV) risk reduction efforts because they have multiple risks for HIV acquisition and transmission. This report presents 1) the demographic characteristics of MSM/IDU diagnosed with acquired immunodeficiency syndrome (AIDS) in 1998 and MSM/IDU living with AIDS as of December 31, 1998; 2) trends in AIDS incidence among MSM/IDU from 1985 to 1998; and 3) information on selected behaviors from interviews of MSM/IDU who had AIDS diagnosed from 1996 to 1998 in 12 states.* The findings indicate that 1) over half of MSM/IDU with AIDS were non-Hispanic blacks and Hispanics, and most MSM/IDU with AIDS were reported from large metropolitan statistical areas (MSAs); 2) AIDS incidence has declined since 1996; and 3) a high prevalence of drug-related and sexual risk behaviors occurred among MSM/IDU with AIDS.

Demographic and risk characteristics of MSM/IDU aged ≥13 years with AIDS reported to CDC were obtained from AIDS surveillance data in the 50 states, the District of Columbia, and all U.S. territories. Risk information for AIDS surveillance generally was obtained from medical records. For this analysis, only persons with the reported dual risk factors for HIV transmission of male-male sex and injecting-drug use were included. AIDS diagnoses were adjusted for reporting delays on the basis of cases reported to CDC through December 1999, and for the anticipated reclassification of cases initially reported without risk (*1,2*).

*Arizona, California, Colorado, Connecticut, Delaware, Florida, Georgia, Michigan, New Jersey, New Mexico, South Carolina, and Washington.

HIV/AIDS — Continued

Information on selected behavioral characteristics of MSM/IDU with AIDS was obtained from the Supplement to HIV/AIDS Surveillance (SHAS) project (*3*). SHAS is a cross-sectional interview study aimed at extending information routinely collected in AIDS surveillance. Persons aged ≥18 years recently reported with HIV/AIDS to the 12 health departments participating in SHAS were interviewed about their sexual and drug-related risk behaviors. Interview data are presented for men who were classified as MSM/IDU on the HIV/AIDS case report or who reported male-male sex and injecting-drug use in the SHAS interview.

Trends Among MSM/IDU

The proportion of all AIDS cases among MSM/IDU decreased from 8% in 1990 to 5% in 1998; 2161 MSM/IDU had AIDS diagnosed in 1998, and 18,133 MSM/IDU were living with AIDS as of December 1998 (Table 1). Most were diagnosed in large MSAs (≥1,000,000 persons) and in the South and West.[†] Non-Hispanic blacks and Hispanics accounted for more than half of each group.

AIDS incidence among MSM/IDU increased steadily from 1985 to 1992, and peaked during 1992–1993 (Figure 1), corresponding with the 1993 expansion of the AIDS surveillance case definition. AIDS incidence declined 37% from 1996 to 1998.

Interviews of MSM/IDU

A total of 513 MSM/IDU who had AIDS diagnosed during 1996–1998 were interviewed for the SHAS project. Of these, 435 (85%) were aged 30–49 years. Non-Hispanic blacks, non-Hispanic whites, and Hispanics accounted for 36%, 42%, and 17%,

*Arizona, California, Colorado, Connecticut, Delaware, Florida, Georgia, Michigan, New Jersey, New Mexico, South Carolina, and Washington.
† n=513.

during the 5 years preceding the interview, 45% had shared needles. Seventy-six percent of MSM/IDU had sex with men during the 5 years preceding the interview, and 43% had sex with women. Nearly half of those who had sex during the year preceding the interview did not always use condoms. However, consistent condom use was higher when the steady sex partner was known to be uninfected: 61% who had vaginal intercourse, 57% who had insertive anal intercourse with a man, and 61% who had receptive anal intercourse with a man during the year preceding the interview said that they had always used condoms. During the 5 years preceding interview, 18%–20% of MSM/IDU exchanged sex for money or drugs.

To assess the degree to which multiple risks are captured in AIDS surveillance, risk classification of the MSM/IDU interviewed in SHAS was examined in AIDS surveillance. Of the 513 MSM/IDU, 352 (69%) were classified as MSM/IDU in AIDS surveillance, 106 (21%) were classified as MSM, 50 (10%) were classified as IDU, and two (0.4%) were classified as having had heterosexual contact or contact with an adult with hemophilia.

Reported by: State and territorial health departments; Div of HIV/AIDS Prevention–Surveillance and Epidemiology, National Center for HIV, STD, and TB Prevention; and an EIS Officer, CDC.

Editorial Note: The findings in this report document continued declines in AIDS incidence among MSM/IDU since 1996, which resulted in large part from increased use of antiretroviral therapies that delay disease progression (*4*) and also reflect earlier decreases in HIV incidence among MSM/IDU. The supplemental interview information in a sample of MSM/IDU with AIDS indicates a high prevalence of drug-related and sexual risk behaviors, including sex with men and women. Previous studies have reported similar findings (*5,6*).

HIV/AIDS — Continued

Differences in the racial/ethnic, age, and regional distribution of incident and prevalent AIDS cases reflect some differences in historical patterns of HIV incidence. Those include the later onset of the HIV epidemic in the South compared with the West and the Northeast, and the increasing impact on racial/ethnic minorities (*7,8*). In addition, differences in AIDS incidence and prevalence may reflect differential access to or use of effective antiretroviral treatments. Integrated surveillance for HIV infection and AIDS characterizes persons more recently infected with HIV (*9*).

Non-Hispanic black and Hispanic men were overrepresented among MSM/IDU, accounting for half of MSM/IDU living with AIDS but 22% of the general male population. Race/ethnicity is not a risk factor for HIV infection; social and economic factors associated with race/ethnicity, such as high poverty rates and unemployment and lack of access to health care, are associated with high rates of risk behavior (*10*).

Behavioral risk information for HIV is important to assure that state/local prevention programs are directed to appropriate populations. If providers do not elicit this information or are reluctant to question patients about their sexual and drug-using behaviors, then information in medical records may underrepresent true risks for HIV in the population. Data from the SHAS interviews show that the AIDS surveillance system may have underestimated the number of MSM/IDU and that the true proportion of AIDS cases attributable to MSM/IDU in 1998 may be 7%.

Because MSM/IDU have multiple risks for HIV infection, they are particularly vulnerable to infection and can transmit HIV across multiple populations, including MSM, IDU, and heterosexual women. Prevention strategies must provide the information, skills, and support necessary to reduce both sexual and drug-related risk behaviors among MSM/IDU, and include access to drug treatment and to prevention case management. Additional research is needed to determine whether risk reduction strategies that have been effective for groups with single risks also are effective for groups with multiple risks. HIV/AIDS disease surveillance supplemented with behavioral surveys will help in planning prevention, treatment, and other services needed to reduce transmission and to improve survival and quality of life for infected persons.

Heat-Related Illnesses, Deaths, and Risk Factors — Cincinnati and Dayton, Ohio, 1999, and United States, 1979–1997

During the summer of 1999, a heat wave* occurred in the midwestern and eastern United States. This period of hot and humid weather persisted from July 12 through August 1, 1999, and caused or contributed to 22 deaths among persons residing in Cincinnati (18 deaths) and Dayton (four deaths). A CDC survey of 24 U.S. metropolitan areas indicated that Ohio recorded some of the highest rates for heat-related deaths during the 1999 heat wave, with Cincinnati reporting 21 per million and Dayton reporting seven per million (CDC, unpublished data, 1999). This report describes four heat-related deaths representative of those that occurred in Cincinnati or Dayton during the 1999 heat wave, summarizes heat-related deaths in the United States during 1979–1997, describes risk factors associated with heat-related illness and death, and recommends preventive measures.

Case Reports

Case 1. In July 1999, a 34-year-old woman with schizophrenia was found dead in a group home in Cincinnati at 9 a.m. A caretaker discovered the decedent lying on the couch of a second-floor living room; two windows were open and fans were blowing. The decedent was last seen alive around noon the previous day. She had a medical history of hypertensive heart disease, asthma, and swelling of the ankles for which she had been taking a diuretic, furosemide. The temperature inside the home at the time of her death was unknown; however, the ambient temperature was 92.1 F (33.4 C) when the decedent was found. Her liver core temperature was 106.2 F (41.2 C). The Hamilton County Coroner's Office attributed the death to heatstroke.

Case 2. In July 1999, an 84-year-old man was found dead in his Dayton residence. He lived alone and was found lying in bed, supine and nude. The doors to his home were locked and all the windows were shut. When the body was discovered, the temperature inside the home was approximately 86 F (30 C). A fan was blowing air toward the ceiling, an air conditioner was present but not running, and the thermostat was set in the heat mode. The temperature in Dayton that day reached >90 F (>32 C) with high humidity. An autopsy report indicated the decedent suffered from arteriosclerosis and hypertensive cardiovascular disease. The Montgomery County Coroner's Office attributed the death to exposure to excessive environmental heat.

Case 3. In July 1999, a 65-year-old man was found in his residence by a neighbor, unresponsive and having seizures. Following transport to the emergency department of a local hospital by the Cincinnati Fire Division, the patient had a rectal temperature of

*Three or more consecutive days of air temperatures ≥90 F (≥32.2 C).

Heat-Related Illnesses — Continued

108 F (42.2 C) and subsequently died. The decedent had a history of chronic alcoholism and hypertensive cardiovascular disease. He lived alone in an attic apartment without air conditioning. The Hamilton County Coroner's Office attributed the death to hypoxic encephalopathy following resuscitation for heatstroke.

Case 4. In August 1999, a 24-year-old man was found lying face down on the living room floor of his Dayton apartment in an early stage of decomposition. The room temperature was 99 F (37.2 C), and the apartment had no air conditioning. The decedent lived alone and was last seen alive 3 days earlier at his home by a neighbor. The decedent had a history of mental illness and depression and had been taking benztropine. The Montgomery County Coroner's report listed the probable cause of death as cardiac arrhythmia caused by hyperthermia resulting from exposure to high environmental temperature.

United States

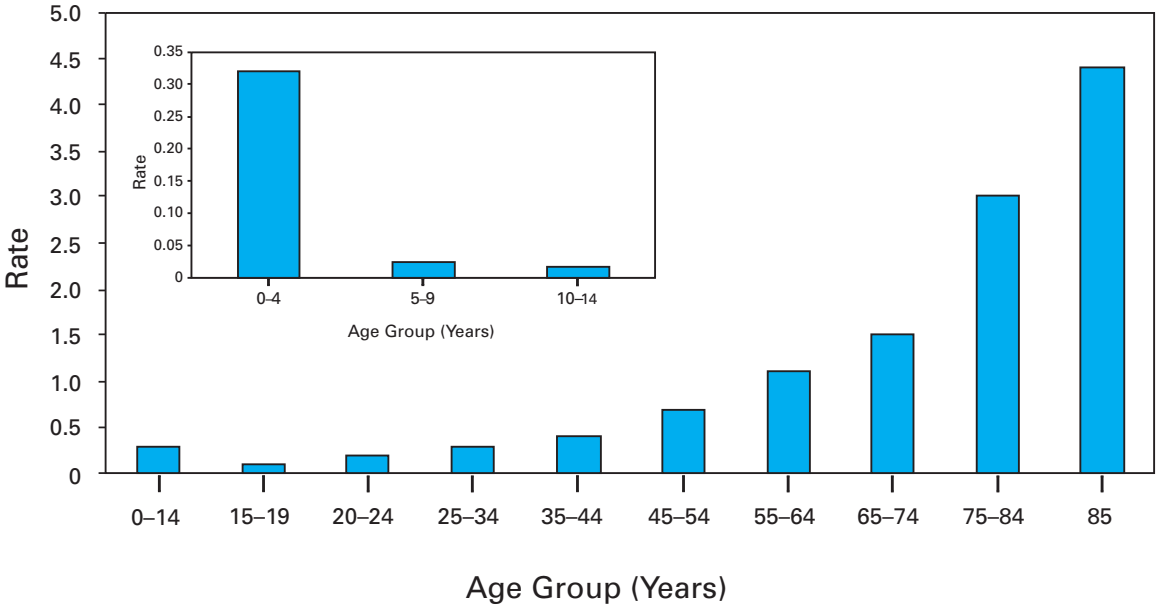
During 1979–1997, the most recent years for which data are available, an annual average of 371 deaths in the United States (*1*) were attributable to "excessive heat exposure"[†] (median: 249; range: 148 in 1979 to 1700 in 1980) (*5*). This translates into a mean annual death rate of 1.5 per million and a median annual death rate of one per million. Because of a record heat wave, the heat-related death rate for 1980 was more than three times higher than that for any other year during the 19-year period. The median annual death rate for hyperthermia in persons aged ≥65 years was three per million. During 1979–1997, 7046 deaths were attributable to excessive heat exposure: 3010 (43%) were "due to weather conditions," 351 (5%) to heat "of manmade origin," and 3683 (52%) "of unspecified origin." Of the 2954 persons whose deaths were caused by weather conditions and for whom age data were available, persons aged ≥65 years accounted for 1783 (44%) deaths, and persons aged ≤14 years accounted for 127 (4%) deaths. Except children aged ≤14 years, the average annual rate of heat-related deaths increased with each age group, particularly for persons aged ≥65 years (Figure 1). During 1979–1997, among persons of all ages, the annual death rate "due to weather conditions" was two times higher for men (0.8 per million) than for women (0.4 per million), and more than three times higher for blacks (1.6 per million) than for whites (0.5 per million). Arizona and Missouri (four per million) and Arkansas and Kansas (three per million) had the highest annual age-adjusted rates for heat-related deaths "due to weather conditions" (*1*).

Reported by: MP Adcock, PhD, City of Cincinnati. WH Bines, MS, Montgomery County; FW Smith, MD, State Epidemiologist, Ohio Dept of Health. Health Studies Br, Div of Environmental Hazards and Health Effects, National Center for Environmental Health; and an EIS Officer, CDC.

[†]The National Association of Medical Examiners' (NAME) definition for heat-related death includes exposure to high ambient temperature either causing the death or as substantially contributing to it, cases where the body temperature at time of collapse was ≥105 F (≥40.6 C), and a history of exposure to high ambient temperature and the reasonable exclusion of other causes of hyperthermia (*1*). Because death rates from other causes (e.g., cardiovascular and respiratory disease) increase during heat waves (*2–4*) (defined by the National Weather Service as ≥3 consecutive days of temperature >90 F [≥32.2 C]), deaths classified as caused by hyperthermia represent only a portion of heat-related death.

Heat-Related Illnesses — Continued

FIGURE 1. Average annual rate* of heat-related deaths†, as the result of weather conditions, by age group — United States, 1979–1997



*Per 1 million population.

† Underlying cause of death attributed to excess heat exposure classified according to the *International Classification of Diseases, Ninth Revision* (ICD-9), as code E900.0 "due to weather conditions (deaths)."

Editorial Note: Behavioral and environmental precautions are essential to preventing illness and death§ associated with heat waves or sustained periods of hot weather (daytime heat index¶ of ≥105 F [≥40.6 C] and a nighttime minimum temperature of 80 F [26.7 C] persisting for at least 48 hours) (*6*).

Illnesses associated with high environmental temperatures include heatstroke (hyperthermia), heat exhaustion, heat syncope, and heat cramps (*2*). Heatstroke is a medical emergency characterized by the rapid onset and increase (within minutes) of the core body temperature to ≥105 F (≥40.6 C), lethargy, disorientation, delirium, and coma (*2*). Heatstroke is often fatal despite rapidly lowering the body temperature (e.g., ice baths), because frequently irreparable neurologic damage has occurred (*2*). Heat exhaustion is characterized by dizziness, weakness, or fatigue often following several days of sustained exposure to hot temperatures, and results from dehydration or electrolyte imbalance (*2*); treatment includes replacing fluids and electrolytes and may require hospitalization (*2*). Physical exertion during hot weather increases the likelihood of heat syncope and heat cramps caused by peripheral vasodilation (*2*). Persons who lose consciousness because of heat syncope should be placed in a recumbent position

§ Underlying cause of death attributed to "excessive heat exposure," classified according to the *International Classification of Diseases, Ninth Revision* (ICD-9), code E900.0, "due to weather conditions" (deaths); code E900.1, "of manmade origin" (deaths); or code E900.9, "of unspecified origin" (deaths). Data were obtained from the Compressed Mortality File of CDC's National Center for Health Statistics, which contains information from death certificates filed in 50 states and the District of Columbia. All rates were age-standardized to the 1990 U.S. population.

¶ Heat index is a measure of the effect of combined elements (e.g., heat and humidity) on the body.

Heat-Related Illnesses — Continued

with feet elevated and given fluid and electrolyte replacement (*2*). For heat cramps, physical exertion should be discontinued and fluids and electrolytes replaced (*2,7*).

All persons are at risk for hyperthermia when exposed to a sustained period of excessive heat (*2*); however, factors that increase the risk for hyperthermia and heat-related death include age (e.g., the elderly), chronic health conditions (e.g., cardiovascular disease or respiratory diseases), mental illness (e.g., schizophrenia), social circumstances (e.g., living alone), and other conditions that might interfere with the ability to care for oneself (*2,3*). Other risk factors are alcohol consumption, which may cause dehydration, previous heatstroke, physical exertion in exceptionally hot environments, the use of medications that interfere with the body's heat regulatory system, such as neuroleptics (e.g., antipsychotics and major tranquilizers), and medications with anticholinergic effects (e.g., tricyclic antidepressants, antihistamines, some antiparkinsonian agents, and some over-the-counter sleep medication [*2–4*]). Persons working in hot indoor or outdoor environments should take 10–14 days to acclimate to high temperatures. Although adequate salt intake is important, salt tablets are not recommended and can be hazardous to some persons (*2*). Although the use of fans may increase comfort at temperatures <90 F (<32.2 C), fans are not protective against heatstroke when temperatures reach ≥90 F (≥32.2 C) and humidity exceeds 35% (*2,4*).

Measures for preventing heat-related illness and death during a heat wave include spending time in air conditioned environments, increasing nonalcoholic fluid intake, exercising only during cooler parts of the day, and taking cool baths (*2*). Elderly persons should be encouraged to take advantage of air conditioned environments (e.g., shopping malls, senior centers, and public libraries), even for part of the day (*2–4*). Public health information about exceptionally high temperatures should be directed toward persons aged ≥65 years and <5 years. Parents should be educated about the heat sensitivity of children aged <5 years (*2*), and should never leave them unattended, especially in motor vehicles. When a heat wave is predicted, friends, relatives, neighbors, and caretakers should check frequently on elderly, disabled, mentally ill, chronically ill, and home-bound persons, and during periods of high temperatures, prevention messages should be disseminated to the public as early and often as possible.

U: Unavailable. -:No reported cases.

*Mortality data in this table are voluntarily reported from 122 cities in the United States, most of which have populations of ≥100,000. A death is reported by the place of its occurrence and by the week that the death certificate was filed. Fetal deaths are not included.

†Pneumonia and influenza.

§Because of changes in reporting methods in this Pennsylvania city, these numbers are partial counts for the current week. Complete counts will be available in 4 to 6 weeks.

¶Total includes unknown ages.

The *Morbidity and Mortality Weekly Report (MMWR)* Series is prepared by the Centers for Disease Control and Prevention (CDC) and is available free of charge in electronic format and on a paid subscription basis for paper copy. To receive an electronic copy on Friday of each week, send an e-mail message to *listserv@listserv.cdc.gov*. The body content should read *SUBscribe mmwr-toc*. Electronic copy also is available from CDC's World-Wide Web server at *http://www.cdc.gov/* or from CDC's file transfer protocol server at *ftp.cdc.gov*. To subscribe for paper copy, contact Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402; telephone (202) 512-1800.

Data in the weekly *MMWR* are provisional, based on weekly reports to CDC by state health departments. The reporting week concludes at close of business on Friday; compiled data on a national basis are officially released to the public on the following Friday. Address inquiries about the *MMWR* Series, including material to be considered for publication, to: Editor, *MMWR* Series, Mailstop C-08, CDC, 1600 Clifton Rd., N.E., Atlanta, GA 30333; telephone (888) 232-3228.
