

Estimates of Deaths Associated with Seasonal Influenza — United States, 1976–2007

Influenza infections are associated with thousands of deaths every year in the United States, with the majority of deaths from seasonal influenza occurring among adults aged ≥ 65 years (1–4). For several decades, CDC has made annual estimates of influenza-associated deaths, which have been used in influenza research and to develop influenza control and prevention policy. To update previously published estimates of the numbers and rates of influenza-associated deaths during 1976–2003 by adding four influenza seasons through 2006–07, CDC used statistical models with data from death certificate reports. National mortality data for two categories of underlying cause of death codes, pneumonia and influenza causes and respiratory and circulatory causes, were used in regression models to estimate lower and upper bounds for the number of influenza-associated deaths. Estimates by seasonal influenza virus type and subtype were examined to determine any association between virus type and subtype and the number of deaths in a season. This report summarizes the results of these analyses, which found that, during 1976–2007, estimates of annual influenza-associated deaths from respiratory and circulatory causes (including pneumonia and influenza causes) ranged from 3,349 in 1986–87 to 48,614 in 2003–04. The annual rate of influenza-associated death in the United States overall during this period ranged from 1.4 to 16.7 deaths per 100,000 persons. The findings also indicated the wide variation in the estimated number of deaths from season to season was closely related to the particular influenza virus types and subtypes in circulation.

The current study extends estimates of influenza-associated deaths from two previous CDC studies (2,3) by adding data from four more influenza seasons for a total of 31 influenza seasons (1976–2007). Estimates are provided for three age groups (<19 years, 19–64 years, and ≥ 65 years) and for two categories of underlying cause of death codes: 1) pneumonia and influenza causes and 2) respiratory and circulatory causes. Deaths from pneumonia and influenza causes are highly correlated with the circulation of influenza (1) and can be considered a lower bound

for deaths associated with influenza (2,4). However, a diagnosis of influenza virus infection often is not confirmed with sensitive and specific laboratory diagnostics, particularly among older persons, and even when identified is rarely recorded on death certificates (5). Many deaths associated with influenza infections occur from secondary infections such as bacterial pneumonia or complications of chronic conditions such as congestive heart failure and chronic obstructive pulmonary disease (6). Therefore, estimates using underlying respiratory and circulatory mortality data (which include pneumonia and influenza causes) can provide an upper bound for influenza-associated deaths (2,7).

Using methods published previously (2,3), CDC estimated the numbers and rates of influenza-associated deaths by virus type and subtype by using Poisson regression models that incorporated weekly national respiratory viral surveillance data. Weekly influenza test results by virus type and subtype were provided by approximately 80 World Health Organization (WHO) and 70 National Respiratory and Enteric Virus Surveillance System (NREVSS) collaborating laboratories in the United States (8). Prominent influenza type and subtype were defined as at least 20% of all isolates that were tested in that season. Mortality data were obtained from the National Vital Statistics System and reflect the underlying cause of death recorded on death certificates (9). Deaths were categorized using the *International Classification of Diseases* eighth revision (ICD-8),

ninth revision (ICD-9), or 10th revision (ICD-10), as appropriate. Weekly estimates of the U.S. population by age group were used as part of the model to correspond to the weekly viral surveillance estimates. All data for deaths with underlying pneumonia and influenza causes and respiratory and circulatory causes were actual counts based on the death certificate ICD codes. To estimate the proportion of deaths that were influenza associated, the average annual number of deaths estimated by the model was divided by the average annual counts of death with underlying pneumonia and influenza causes and respiratory and circulatory causes.

For deaths with underlying pneumonia and influenza causes during 1976–2007 in the United States, the models estimated an annual overall average of 6,309 (range: 961 in 1986–87 to 14,715 in 2003–04) influenza-associated deaths (Table 1). For these underlying causes, the average annual rate of influenza-associated death was 2.4 deaths per 100,000 (range: 0.4–5.1).

Among persons aged <19 years, an estimated annual average of 97 (range: 41 in 1981–82 to 234 in 1977–78) influenza-associated deaths with underlying pneumonia and influenza causes occurred (Table 1). The average annual rate of influenza-associated deaths

for this age group was 0.1 deaths per 100,000 persons (range: 0.1–0.3). Among adults aged 19–64 years, an estimated annual average of 666 (range: 173 in 1981–82 to 1,459 in 2004–05) influenza-associated deaths with underlying pneumonia and influenza causes occurred. The average annual rate of influenza-associated deaths for this age group was 0.4 deaths per 100,000 persons (range: 0.1–0.8). Among adults aged ≥65 years, an estimated annual average of 5,546 (range: 673 in 1978–79 to 13,245 in 2003–04) influenza-associated deaths with underlying pneumonia and influenza causes occurred. The average annual rate of influenza-associated deaths for this age group was 17.0 deaths per 100,000 (range: 2.4–36.7). Deaths among persons aged ≥65 years accounted for 87.9% of the overall estimated average annual influenza-associated deaths with underlying pneumonia and influenza causes.

For deaths with underlying respiratory and circulatory causes (including pneumonia and influenza causes) during 1976–2007, the models estimated an annual U.S. average overall of 23,607 (range: 3,349 in 1986–87 to 48,614 in 2003–04) influenza-associated deaths (Table 2). For these underlying causes, the average annual rate of influenza-associated death was 9.0 deaths per 100,000 (range: 1.4–16.7).

* Deaths were categorized using the *International Classification of Diseases* eighth revision (ICD-8), ninth revision (ICD-9), or 10th revision (ICD-10), as appropriate.

[†] Prominent influenza type and subtype were defined as at least 20% of all isolates that were typed or subtyped in that season.

[§] Confidence interval.

Among persons aged <19 years, an estimated annual average of 124 (range: 57 in 1981–82 to 197 in 1977–78) influenza-associated deaths with underlying respiratory and circulatory causes occurred (Table 2). The average annual rate of influenza-associated deaths for this age group was 0.2 deaths per 100,000 persons (range: 0.1–0.3). Among adults aged 19–64 years, an estimated annual average of 2,385 (range: 504 in 1981–82 to 4,752 in 2003–04) influenza-associated deaths with underlying respiratory and circulatory causes occurred. The average annual rate of influenza-associated deaths for this age group was 1.5 deaths per 100,000 persons (range: 0.4–3.1). Among adults aged ≥65 years, an estimated annual average of 21,098 (range: 2,344 in 1986–87 to 43,727 in 2003–04) influenza-associated deaths with underlying respiratory and circulatory causes occurred. The

average annual rate of influenza-associated deaths for this age group was 66.1 deaths per 100,000 (range: 8.0–121.1). Deaths among persons aged ≥65 years accounted for 89.4% of the overall estimated average annual influenza-associated deaths with underlying respiratory and circulatory causes.

For both causes, the average mortality rates for the 22 seasons during which influenza A(H3N2) was a prominent strain were 2.7 times higher than for the nine seasons that it was not. The average annual number of influenza-associated deaths during influenza A(H3N2) prominent seasons was 7,722 for pneumonia and influenza causes and 28,909 for respiratory and circulatory causes, compared with 2,856 deaths for pneumonia and influenza causes and 10,648 deaths for respiratory and circulatory causes in seasons in which it was not.

TABLE 2. Estimated number of annual influenza-associated deaths with underlying respiratory and circulatory causes,* by age group — United States, 1976–77 through 2006–07 influenza seasons

* Includes cause of death codes for influenza and pneumonia. Deaths were categorized using the *International Classification of Diseases* eighth revision (ICD-8), ninth revision (ICD-9), or 10th revision (ICD-10), as appropriate.

[†] Prominent influenza type and subtype were defined as at least 20% of all isolates that were typed or subtyped in that season.

[§] Confidence interval.

The distribution of mortality across age groups was similar for the two groups of coded deaths. For pneumonia and influenza causes, the proportions of average deaths overall were 1.5%, 10.6%, and 87.9% for persons aged <19 years, 19–64 years, and ≥65 years, respectively. For respiratory and circulatory causes, the proportions were 0.5%, 10.1%, and 89.4%.

Based on an average annual count of 74,363 for all pneumonia and influenza deaths, and an average annual estimate of 6,309 deaths associated with influenza in this category, 8.5% of all pneumonia and influenza deaths were influenza associated. Based on an annual average count of 1,132,319 for all respiratory and circulatory deaths and an average annual estimate of 23,607 deaths associated with influenza in

this category, 2.1% of all respiratory and circulatory deaths were influenza associated.

Editorial Note

This report updates estimates of the number of influenza-associated deaths from the 1976–77 through 2006–07 influenza seasons and demonstrates the substantial variability in mortality estimates by year, influenza virus type/subtype, and age group. The estimated rates of influenza-associated hospitalizations

What is already known on this topic?

Influenza infections result in substantial medical costs, hospitalizations, lost productivity, and thousands of deaths every year in the United States with the majority of deaths from seasonal influenza occurring among adults aged ≥ 65 years.

What is added by this report?

During 1976–2007, annual estimates of influenza-associated deaths from respiratory and circulatory causes ranged from 3,349 (in 1986–87) to 48,614 (in 2003–04), and the annual rate of influenza-associated death for all ages ranged from 1.4 to 16.7 deaths per 100,000 persons; during seasons when influenza A(H3N2) circulating strains were prominent, 2.7 times more deaths occurred compared with seasons when A(H3N2) was not prominent.

What are the implications for public health practice?

A single estimate should not be used to summarize influenza-associated deaths; a range of estimates should be described in the context of circulating virus strains and underlying causes of death among age groups. Annual influenza vaccination (now recommended for all persons aged ≥ 6 months) is the best way to avoid influenza complications, and prompt treatment with antiviral medications can reduce the risk for severe illness and death among persons at increased risk for influenza or who are hospitalized with influenza.

and deaths vary substantially from one influenza season to the next, depending, in part, on the characteristics of the circulating influenza virus strains (10). Because of this variability, a single estimate cannot be used to summarize influenza-associated deaths. This report provides estimates for two categories of underlying cause of death codes, pneumonia and influenza causes and respiratory and circulatory causes; if only one category is used to summarize the mortality effects of influenza, the respiratory and circulatory data likely provide the most accurate estimates. During the past three decades, the estimated number of annual influenza-associated deaths from respiratory and circulatory causes ranged from a low of 3,349 to a high of 48,614 deaths.

A previous study (2) presented an average annual estimate of 25,420 influenza-associated respiratory and circulatory deaths during a 23-season period; this study estimated an average of 23,607 annual influenza-associated deaths using the same model but over a 31-year period. The findings in this report are similar to those of previous CDC studies (2,3) and other cross-decade studies that used similar models (4,7).

When describing the severity of seasonal influenza epidemics, examining seasons with the same circulating influenza virus type is useful. For example, during seasons with prominent circulation of influenza A(H3N2) viruses, 2.7 times more deaths occurred than during seasons when A(H3N2) viruses were not prominent. An annual estimate of 36,155 influenza-associated respiratory and circulatory deaths often is quoted from an earlier CDC study (2); however, that average was calculated for the period 1990–1999, when more severe influenza A(H3N2) viruses were prominent for eight of the nine seasons.

Variations in influenza-associated mortality by age group also should be noted. As reported in this and other studies (2,3), approximately 90% of influenza-associated deaths occur among adults aged ≥ 65 years. An estimated annual average of 124 persons aged < 19 years and 2,385 aged 19–64 years die from influenza-associated respiratory or circulatory causes. Future research that considers years-of-life-lost is needed to better communicate the mortality burden of influenza in these younger populations. Future research also is needed to estimate and communicate the risk for influenza-associated mortality among different demographic and health risk groups.

The findings in this report are subject to at least four limitations. First, the models do not account for cocirculating pathogens such as respiratory syncytial virus (RSV). Future research should replicate and extend models that distinguish between deaths associated with influenza versus RSV (2). Second, estimates over time might not be comparable because the influenza virus surveillance data used to model mortality rely on national influenza testing practices, which have changed over the past decade (8). Future research should consider how trends in testing practices can be included in these models and cross-season estimates of influenza-associated mortality. Third, increases in the U.S. population aged ≥ 65 years during the study period could have contributed to a general increase in influenza-associated mortality. Age-adjusting future estimates or estimating deaths in smaller age categories among older adults could address this issue. Finally, because the estimates made in this report rely on national death certificate data and these data currently are available only through 2007, preliminary estimates of 2009 influenza A(H1N1)-associated deaths are not directly comparable with these results.*

*CDC estimates of 2009 H1N1 deaths are available at http://www.cdc.gov/h1n1flu/estimates_2009_h1n1.htm.

Debate will continue regarding the most appropriate statistical models and cause of death categories to use in estimating the number of influenza-associated deaths (1,7). This study's provision of estimates for more narrow (pneumonia and influenza causes) and more broad (respiratory and circulatory causes) categories continues the strategy of comparing and contrasting results from different models as advocated by CDC (1–3) and others (7).

Influenza infections are associated with substantial medical costs, hospitalizations, lost productivity, and thousands of deaths every year in the United States. Annual influenza vaccination is the best way to reduce the risk for complications from influenza infections and is now recommended for all persons aged ≥ 6 months in the United States. Prompt treatment with influenza antiviral medications can reduce the risk for severe illness and death among persons at increased risk for influenza or who are hospitalized with suspected or confirmed influenza.

Tobacco Use Among Middle and High School Students — United States, 2000–2009

Tobacco use continues to be the single leading preventable cause of death and disease in the United States (1). More than 80% of established adult smokers begin smoking before age 18 years (2). To monitor trends in tobacco use among middle and high school students, CDC analyzed 2000–2009 data from the National Youth Tobacco Survey (NYTS), a school-based survey that collects information on tobacco use and related behaviors and attitudes from middle school (grades 6–8) and high school (grades 9–12) students. This analysis indicated that in 2009, 8.2% of middle school students and 23.9% of high school students reported current use of any tobacco product; 5.2% of middle school students and 17.2% of high school students reported current use of cigarettes. Overall prevalence did not decrease from 2006 to 2009 for use of any tobacco product among either group. During 2000–2009, the prevalence of current tobacco use among middle school students declined (15.1% to 8.2%), as did current cigarette use (11.0% to 5.2%) and cigarette smoking experimentation (29.8% to 15.0%). Similar trends were observed for high school students (current tobacco use: 34.5% to 23.9%; current cigarette use: 28.0% to 17.2%; cigarette smoking experimentation: 39.4% to 30.1%). Overall, no change in susceptibility to initiate cigarette smoking was observed for either group. To further decrease tobacco use and susceptibility to use among youths, restrictions on advertising, promotion, and availability of tobacco products to youths should be combined with full implementation of evidence-based, communitywide, comprehensive tobacco control policies (3–5).

NYTS includes measures on prevalence of youth tobacco use, smoking cessation, tobacco-related knowledge and attitudes, access to tobacco, media and advertising, and secondhand smoke exposure and has been conducted approximately every 2 years since 2000 (6). The 2009 NYTS used a three-stage cluster sampling procedure to generate a cross-sectional, nationally representative sample of students in grades 6–12 from all 50 states and the District of Columbia. Of 222 randomly selected schools, 205 (92.3%) participated; of 24,666 students randomly selected at the participating schools, 22,679 (91.9%) participated, yielding an overall response rate of 84.8% (school response rate ×

student participation rate). During 2000–2009, overall response rates ranged from 74.2% in 2002 to 84.8% in 2009. In all years, middle and high school students were asked to complete a self-administered, pencil and paper questionnaire in a classroom setting.

Respondents were asked about their use of cigarettes, cigars, smokeless tobacco, pipes, bidis (small brown cigarettes wrapped in a leaf), and kreteks (clove cigarettes) within the last 30 days. Each type of tobacco was asked about individually. For each substance, current use was defined as use on at least 1 of the past 30 days. Cigarette smoking experimentation was defined as having ever smoked any cigarettes, even one or two puffs, but fewer than 100 cigarettes (7). Cigarette smoking experimentation and current cigarette use are not mutually exclusive. A person who is an experimenter might or might not be classified as a current smoker. Those who were susceptible to initiate cigarette smoking were defined as never smokers (never tried smoking cigarettes, even one or two puffs) who reported being open to trying cigarette smoking* (7).

Data were adjusted for nonresponse and weighted to provide national prevalence estimates while accounting for the complex survey design; 95% confidence intervals were calculated. Differences in point estimates between the 2006 NYTS[†] and the 2009 survey were assessed using a two-tailed t-test at a $p < 0.05$ significance level. Logistic regression was used to analyze temporal changes during 2000–2009 for middle and high school students. For this 10-year trend analysis, results were adjusted for grade, race/ethnicity, and sex to control for any changes in population composition during this period. Results were assessed for the presence of linear trends; $p < 0.05$ was used to determine statistical significance. A test for linear trend will be significant if an overall decrease or increase occurs during the study period. If a linear

* Susceptibility to initiate cigarette smoking among never smokers was defined as providing any response other than “no” to the question, “Do you think that you will try a cigarette soon?” and any response other than “definitely not” to the questions, “Do you think you will smoke a cigarette anytime during the next year?” and “If one of your best friends offered you a cigarette, would you smoke it?”

trend was detected, data also were assessed for the presence of a quadratic trend; a significant quadratic trend indicates that the rate of change accelerates or decelerates across the study period.

In 2009, 8.2% of middle school students and 23.9% of high school students reported current use of any tobacco product, and 5.2% of middle school students and 17.2% of high school students reported current use of cigarettes (Table). Among middle school students, the most commonly used forms of tobacco other than cigarettes were cigars (3.9%), smokeless tobacco (2.6%), pipes (2.3%), bidis (1.6%), and kreteks (1.2%). Among high school students, the most commonly used other forms of tobacco were cigars (10.9%), smokeless tobacco (6.7%), pipes (3.9%), kreteks (2.4%), and bidis (2.4%). Susceptibility to

initiate cigarette smoking was 21.2% in middle school students and 24.0% in high school students.

Prevalence did not change from 2006 to 2009 for any of these measures for either middle school students or high school students overall. Decreases were noted only among middle school students for current cigarette use in females (6.4% to 4.7%) and in non-Hispanic whites (6.5% to 4.3%) (Table). Among high school students, declines were observed only in females for current tobacco use (21.3% to 18.2%) and current cigarette use (18.4% to 14.8%); and in non-Hispanic whites for current bidi use (2.6% to 1.7%).

From 2000 to 2009, among middle school students, declines were observed for current tobacco use (15.1% to 8.2%), current cigarette use (11.0% to 5.2%), and cigarette smoking experimentation (29.8% to 15.0%). For these three measures, after

adjusting for grade, race/ethnicity, and sex, the overall declines remained. The quadratic analyses did not show changes in the rates of decline within the study period (Figure 1). No overall decline in susceptibility to smoking among middle school students was observed for the study period. Similarly, from 2000 to 2009, among high school students, declines were observed for current tobacco use (34.5% to 23.9%), current cigarette use (28.0% to 17.2%), and experimentation (39.4% to 30.1%). After adjusting for grade, race/ethnicity and sex, the overall declines

remained. The quadratic analyses did not show changes in the rates of decline within the study period (Figure 2). During this same period, no overall decline in prevalence of susceptibility to smoking among high school students was observed.

Editorial Note

The findings in this report indicate that, from 2000 to 2009, prevalences of current tobacco and cigarette use and experimentation with smoking cigarettes declined for middle school and high school students, but no overall declines were noted for the 2006–2009 period. Declines were seen only for a few measures within a few population subgroups. The general lack of significant change during the shorter period indicates that the current rate of decline in tobacco use is relatively slow. These findings are consistent with the findings from the national Youth Risk Behavior Survey (YRBS) for recent years (8). Although NYTS was not administered before 2000, YRBS results indicate that the rate of decline in youth smoking was slower during 2003–2009 than during 1997–2003, and that these declines follow years of increase in prevalence of youth cigarette use in the 1990s (8). Cigarette use among high school students remains above the *Healthy People 2010* target of $\leq 16\%$

prevalence, and overall tobacco use remains above the target of no more than 21% prevalence.[§]

The overall point prevalence estimates for current high school smoking differed slightly between the NYTS (17.2%) and the national YRBS (19.5%) (8) in 2009, the only year in which both surveys were conducted. The observed differences might be the result of variation between the samples of schools selected for the survey, differences in response rates, or student reactions to the single topic context of NYTS versus the multiple-topic context of YRBS. The two surveys are complementary. The national YRBS measures other youth risk behaviors that are public health priorities and that are used to track *Healthy People 2010* objectives, whereas the NYTS focuses specifically on tobacco related indicators and includes additional measures not included on the national YRBS: use of pipes, bidis, and kreteks, access to products, exposure to advertisements, and susceptibility to initiation of cigarette smoking.

The lack of change in susceptibility to try cigarette smoking might help explain the recent slowing in decline in current smoking (8). Susceptibility indicates the proportion of youths who are willing to experiment with cigarette use (9) and is an important indicator of the effectiveness of tobacco control policies. The findings from this report suggest further efforts are needed to counter tobacco industry influences on youths. New Food and Drug Administration (FDA) regulations which prohibit the distribution of free samples of cigarettes and restrict the distribution of free samples of smokeless tobacco to youths, and prohibit tobacco brand name sponsorship of any athletic, musical or other social or cultural events, are designed to help prevent tobacco use among youths.[¶] Broader tobacco-control policies, such as tobacco-free policies, tobacco tax increases, and advertisement restrictions are needed to further reduce youth and adult tobacco use (4).

The findings in this report are subject to at least three limitations. First, because NYTS began in 2000, trend analyses cannot capture the increases in youth cigarette use that occurred in the early 1990s nor the faster rate of decline that was observed by YRBS for the late 1990s compared with more recent years. Second, the data were collected from youths who attended middle or high schools and might not be representative of all youths in the United States; youths who have dropped out of

What is already known on this topic?

Smoking continues to be the leading preventable cause of death and disability in the United States; and among adult established smokers in the United States, more than 80% began smoking before age 18 years.

What is added by this report?

From 2000 to 2009, prevalences of current tobacco and cigarette use and experimentation with smoking cigarettes have declined for middle school and high schools students but no overall significant declines were noted from 2006–2009. The proportions of middle school and high school students who have never tried cigarette smoking but are open to trying cigarette smoking have not changed significantly in the past 9 years.

What are the implications for public health practice?

To further decrease tobacco use and susceptibility to use among youths, restrictions in advertising, promotions, and the commercial availability of tobacco products should be combined with full implementation of evidence-based, communitywide, comprehensive tobacco control policies.

school are more likely to smoke than are youths who are in school (10). Finally, response and recall bias might have been introduced because the data are self-reported; however, similar questions on YRBS showed good test-retest reliability (8).

Although comprehensive tobacco control programs are effective in decreasing tobacco use in the United States, they remain underfunded.** Based on estimates obtained from the Campaign for Tobacco Free Kids for fiscal year 2010, only one state (North Dakota) achieved the funding level recommended by CDC in 2007.†† The more states spend on sustained comprehensive tobacco control programs, the greater the reductions in youth and adult smoking rates (3,4). Comprehensive tobacco control programs should be fully funded and implemented, as recommended by CDC (3,4). In addition, enforcement of the new FDA regulations and the Family Smoking Prevention and Tobacco Control Act^{§§} provisions, which require larger, graphic health warnings on cigarette packages and in advertisements, restrict access to tobacco by youths, and restrict certain other forms of advertising and promotion attractive to youths, could change social norms concerning cigarette and other tobacco use (4). Changes in social norms might help reduce youth susceptibility to

Changes in Measurement of *Haemophilus influenzae* serotype b (Hib) Vaccination Coverage — National Immunization Survey, United States, 2009

The National Immunization Survey (NIS) has introduced a new method for measuring *Haemophilus influenzae* serotype b (Hib) vaccination coverage. Since its inception in 1994, NIS has considered a child aged 19–35 months to be fully vaccinated with Hib vaccine if the child had received 3 or more doses of any Hib-containing vaccine (3+Hib), regardless of vaccine product type received. However, for some Hib vaccine product types, 4 doses are needed to be fully vaccinated. Because NIS data have not distinguished between Hib vaccine product types, a child who received 3 doses of a vaccine product that requires 4 doses was misclassified as fully vaccinated. Since January 2009, NIS has requested that vaccination providers report data on Hib vaccine product types. Using this new information, two new measures were created: 1) primary series completed and 2) fully vaccinated (primary series completed plus booster dose). To determine the effects of the new method, CDC used preliminary data from the first half of 2009 NIS to compare the new measures with the previous 3+Hib measure. The findings, which were influenced by a nationwide shortage of certain Hib vaccine types, indicated that 92.9% of children aged 19–35 months in the United States had received the primary Hib series according to interim recommendations of the Advisory Committee on Immunization Practices (ACIP), and 56.9% were fully vaccinated. Using the previous method, 82.9% were fully vaccinated (3+Hib). When interpreting Hib vaccination coverage estimates and analyzing trends with NIS Hib vaccination coverage data in the future, analysts and state immunization programs should be aware of this change in Hib measurement.

Before 2009, two manufacturers produced Hib vaccines licensed for children in the United States: Merck & Co., Inc. (West Point, Pennsylvania) and Sanofi Pasteur (Swiftwater, Pennsylvania). Merck's Hib vaccines require a 2-dose primary series with doses at ages 2 months and 4 months and a booster at age 12–15 months. Sanofi Pasteur's Hib vaccines require a 3-dose primary series at ages 2, 4, and 6 months and a booster at age 12–15 months. Before January 2009, NIS did not request Hib vaccine product type and considered fully vaccinated

with Hib vaccine all children who had received 3 or more doses of any Hib-containing vaccine.

In December 2007, Merck recalled several lots of two types of Hib conjugate vaccine and temporarily suspended production of both products, leading to a shortage of Hib conjugate vaccines during December 2007–September 2009. The recalled vaccines were PedvaxHIB, a monovalent Hib vaccine, and Comvax, a Hib-hepatitis B (HepB) combination vaccine. Because of the limited Hib vaccine supply, ACIP recommended temporary suspension of the booster dose for most children in the United States* (1). This revised recommendation underscored an NIS measurement problem; a child who received the 2-dose primary series with a Merck product in accordance with the revised recommendation would not be counted as fully vaccinated according to the 3+Hib measure, whereas a child who received a 3-dose primary series with a Sanofi Pasteur product in accordance with the revised recommendation would be counted as fully vaccinated according to the 3+Hib measure.

NIS is an ongoing, national survey used to estimate vaccination coverage in the United States among children aged 19–35 months in the 50 states and selected local areas and, beginning in 2009, in the U.S. Virgin Islands. NIS is a random-digit-dialed telephone survey of households with children aged 19–35 months at the time of interview. The household telephone survey is followed by the Immunization History Questionnaire,[†] which is mailed to a child's vaccination providers, if permission is granted by the parent or guardian. Beginning in January 2009, the names of the Hib vaccine product types were added to the Immunization History Questionnaire[§] (2).

*Groups recommended to continue to receive the booster dose included children at high risk (i.e., children with asplenia, sickle cell disease, human immunodeficiency virus infection and certain other immunodeficiency syndromes, and malignant neoplasms), and American Indian/Alaska Native (AI/AN) children. In addition, providers who served predominantly AI/AN children living in AI/AN communities were recommended to continue using the Merck PedvaxHIB product, which was only available from the Vaccines for Children pediatric vaccine stockpile during the shortage.

[†] Available at http://www.cdc.gov/nis/pdfs/nis_ihq.pdf.

[§] In October 2009, the Hib vaccine Hiberix (GlaxoSmithKline Biologicals, Rixensart, Belgium) was added to the Immunization History Questionnaire after licensure for use as a booster dose.

With the addition of vaccine product type information, two new measures of Hib vaccination coverage were created: 1) vaccinated with the primary series and 2) vaccinated with the primary series and a booster dose (fully vaccinated). According to ACIP vaccination recommendations, children who receive a mixture of vaccine product types require 3 doses to complete the primary series (3). The two new measures are presented in this report and compared with the 3+Hib measure in reports published previously (4).

For this report, a subset of 2008–09 between-year NIS data was analyzed, consisting of children with interviews in 2009. Interviews for the entire between-year NIS were conducted from July 2, 2008 to August 11, 2009, based on the NIS samples drawn for the third quarter of 2008 through the second quarter of 2009. The household Council of American Research Organizations (CASRO) response rate for the between-year data was 63.3%; provider vaccination records were obtained for 70.4% (n = 18,032 children). Of these, 8,122 children with interviews conducted in the 50 states and District of Columbia during January–June 2009 and with adequate provider data reported by the end of October 2009 were selected for this analysis. This subset consisted of children born during January 9, 2006 through December 19, 2007; 52% of the children were younger than 12 months at the beginning of the Hib shortage and thus were more likely to have had their booster doses deferred. Data were weighted to adjust for households with multiple telephone lines, household nonresponse, and exclusion of households without landline telephones (4).

For some children and certain Hib vaccine doses, product type was not reported. For the estimate of the percentage completing the primary series, 0.9% of children were missing vaccine type information for their first or second Hib dose. For the estimate of the percentage completing the primary series and booster dose, 4.9% of children had missing vaccine type information. The two measures were estimated assuming the Hib vaccines with missing type information were a type requiring 3 doses for the primary series, thereby producing a conservative estimate of coverage.

Using the measures, among children aged 19–35 months overall in the United States, 92.9% received the primary Hib series according to interim ACIP recommendations, and 56.9% were fully vaccinated. Using the previous method, 82.9% were fully vaccinated (3+Hib) (Table). Among states, the percentage completing the primary Hib series ranged from 82.3% in Montana to 98.0% in Alabama, and the percentage fully vaccinated with Hib ranged from 32.6% in West Virginia to 82.7% in Alaska. Using the previous measure, the percentage fully vaccinated (3+Hib) ranged from 50.9% in Rhode Island to 97.7% in New Hampshire.

The Hib vaccine shortage of December 2007–September 2009 made evident the importance of accounting for product type in measuring Hib vaccination coverage. These data show that the previous method of measuring Hib vaccination coverage (3+Hib) underestimated coverage with the primary series but overestimated coverage with the primary series and booster. Use of vaccine product type information indicated a wide range of coverage with the primary series and booster among the states.

Ascertainment of product type for Hib in NIS was successful. Less than 5% of children had missing vaccine product types for determining Hib vaccination coverage for the primary series and booster. NIS also now requests that providers report vaccine product type for rotavirus vaccine (2 or 3 dose schedule, depending on type); rotavirus coverage will be routinely reported by NIS beginning in fall 2010.

In the future, routine reporting of national and state vaccination coverage levels will include the more valid measures of Hib status, based on product types. CDC also plans to use the full year of 2009 NIS data to evaluate 1) compliance with interim recommendations (deferring the booster dose) during the December 2007–September 2009 Hib vaccine shortage, 2) reasons for the wide range in coverage levels across states during the shortage period, and 3) the number of children receiving catch-up vaccinations with the deferred booster dose once the shortage resolved (5).

* A subset of 2008–09 between-year NIS data was analyzed, consisting of children with interviews during January–June 2009. Interviews for the entire between-year NIS were conducted from July 2, 2008, to August 11, 2009, based on the NIS samples drawn for the third quarter of 2008 through the second quarter of 2009. The 8,122 children in the subset analyzed had birthdates from January 9, 2006, through December 19, 2007.

[†] Under the previous measure, children were considered fully vaccinated if they had 3 or more doses of Hib vaccine of any type.

[§] Children are considered to have completed the primary series if they received either 3 or more doses of any type of Hib vaccine or 2 doses of Hib vaccine and both were Merck products. A Hib vaccine reported with an unknown type was assumed to not be a Merck product.

[¶] Under this new measure, children are considered fully vaccinated if they received either 4 or more doses of any type of Hib vaccine, or if they received 3 doses of Hib and the first 2 of those doses were Merck products, with the third dose of any type. Hib vaccines reported with unknown types for the first 2 doses were assumed to not be Merck products.

** Confidence interval.

^{††} Estimate might be unreliable because confidence interval is >20.

Notes from the Field

Measles Transmission Associated with International Air Travel — Massachusetts and New York, July–August 2010

On July 8, 2010, the Massachusetts Department of Public Health (MDPH) notified CDC of a case of laboratory-confirmed measles in an unvaccinated airline passenger aged 23 months (1). The child had arrived hours earlier on a flight from Switzerland and was contagious during the flight. After obtaining the flight manifest, CDC shared locating information with relevant state health departments; of 31 passengers considered exposed (i.e., seated within two rows and any infant seated anywhere on the airplane), 29 (94%) were notified.

On July 28, the New York State Department of Health (NYSDOH) notified CDC and MDPH that one of the airline contacts had developed laboratory-confirmed measles. The ill traveler came to the United States as a chaperone for students from Europe and Asia attending an educational program. During July 20–23 (while contagious and before being isolated), he exposed 270 students and counselors in Massachusetts and New York. Member of this group were scheduled to return to their home countries from July 30 through August 6. Because exposed, susceptible persons who are incubating measles might be infectious 5–21 days after initial exposure, the surveillance period was determined to be until August 14 (2,3). CDC Quarantine Stations in Boston and New York worked with NYSDOH and MDPH to assess the immune status of contacts before permitting them to fly. Presumptive evidence of immunity to measles was defined as 1) documentation of at least 1 dose of measles-containing vaccine or 2) serologic evidence of immunity.

Of the 270 persons considered exposed, 268 (99%) were cleared to fly as scheduled: 242 provided documentation of vaccination and 26 had serologic evidence of immunity. Two persons lacked evidence

of immunity and voluntarily postponed their departures until the end of the surveillance period. CDC requested that the airlines waive any fees for changing flights. No febrile rash illnesses have been reported among exposed persons.

To prevent the spread of measles, international travelers are encouraged to have evidence of measles immunity. Persons with measles or those who might be incubating measles should avoid travel aboard commercial airlines until they are no longer infectious. Organizations hosting international students should consider asking participants to provide documentation of adequate vaccination.

Reported by

Announcement

Epidemic Intelligence Service Application Deadline — September 15, 2010

The Epidemic Intelligence Service (EIS) is a 2-year, postgraduate program of service and on-the-job training for health professionals interested in the practice of epidemiology. Each year, EIS provides approximately 80 persons from around the world opportunities to gain hands-on experience in epidemiology at CDC or state or local health departments. EIS officers, often called CDC's "disease detectives," have assumed leadership positions at CDC and other public health agencies. The EIS experience also is useful for health professionals who would like to gain a population-based perspective on public health practice.

Persons with a strong interest in applied epidemiology who meet at least one of the following qualifications may apply to EIS: 1) physicians with >1 year of clinical training; 2) persons with a doctoral degree in epidemiology, biostatistics, the social or behavioral sciences, natural sciences, or the nutrition sciences; 3) dentists, physician assistants, and nurses with a master of public health (MPH) or equivalent degree; 4) veterinarians with an MPH or equivalent degree or relevant public health experience.

Deadline for submitting applications for the July 2011–June 2013 EIS program is September 15, 2010. Application information and EIS program details are available at <http://www.cdc.gov/eis/index.html>, by telephone (404-498-6110), or via e-mail (eisepo@cdc.gov).

Erratum: Vol. 58, No. RR-2

In the report, "Prevention of Rotavirus Gastroenteritis Among Infants and Children: Recommendations of the Advisory Committee on Immunization Practices (ACIP)," an error occurred in a confidence interval in the last sentence of the fourth paragraph on page 6. The sentence should read, "Among the limited number of infants from phase III trials who received at least 1 dose of RV5 (n = 144) or placebo (n = 135) >10 weeks after a previous dose, the estimate of efficacy of the RV5 series for protection against G1–G4 rotavirus gastroenteritis of any severity was 63% (CI = -53%–94%) (94)."

QuickStats

FROM THE NATIONAL CENTER FOR HEALTH STATISTICS

Outpatient Colonoscopy Procedure Rates,* by Age Group — National Survey of Ambulatory Surgery, United States, 1996 and 2006

* Per 10,000 population, based on U.S. Census Bureau civilian population as of July 1, 1996 and July 1, 2006. Colonoscopy procedures are assigned codes 45.23 and 45.25 under the *International Classification of Diseases, Ninth Revision, Clinical Modification* and are performed in hospital-based and freestanding ambulatory surgery facilities. The majority of colonoscopies (up to 90% in 2006) take place in ambulatory settings compared with inpatient facilities; no change in the colonoscopy rate in inpatient facilities was observed from 1996 to 2006.

† 95% confidence interval.

From 1996 to 2006, the rate of outpatient colonoscopy procedures increased for adults aged ≥ 50 years. For persons aged 50–64 years, the rate in 2006 was 3.5 times higher than the rate in 1996 (472.4 versus 132.2 procedures per 10,000 population), and for those aged 65–74 years, the rate was nearly three times higher (638.5 versus 216.2). For persons aged 75–84 years, the rate in 2006 was more than twice the rate in 1996 (517.3 versus 230.5), and for persons aged ≥ 85 years, the increase was approximately double (173.6 versus 96.9).

TABLE I. (Continued) Provisional cases of infrequently reported notifiable diseases (<1,000 cases reported during the preceding year) — United States, week ending August 21, 2010 (33rd week)*

—: No reported cases. N: Not reportable. NN: Not Nationally Notifiable Cum: Cumulative year-to-date counts.
 * Incidence data for reporting years 2009 and 2010 are provisional, whereas data for 2005 through 2008 are finalized.
 † Calculated by summing the incidence counts for the current week, the 2 weeks preceding the current week, and the 2 weeks following the current week, for a total of 5 preceding years. Additional information is available at <http://www.cdc.gov/ncphi/diss/nndss/phs/files/5yearweeklyaverage.pdf>.
 ‡ Not reportable in all states. Data from states where the condition is not reportable are excluded from this table except starting in 2007 for the domestic arboviral diseases, STD data, TB data, and influenza-associated pediatric mortality, and in 2003 for SARS-CoV. Reporting exceptions are available at <http://www.cdc.gov/ncphi/diss/nndss/phs/infdis.htm>.
 ¶ Includes both neuroinvasive and nonneuroinvasive. Updated weekly from reports to the Division of Vector-Borne Infectious Diseases, National Center for Zoonotic, Vector-Borne, and Enteric Diseases (ArboNET Surveillance). Data for West Nile virus are available in Table II.
 ** Data for *H. influenzae* (all ages, all serotypes) are available in Table II.
 †† Updated monthly from reports to the Division of HIV/AIDS Prevention, National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention. Implementation of HIV reporting influences the number of cases reported. Updates of pediatric HIV data have been temporarily suspended until upgrading of the national HIV/AIDS surveillance data management system is completed. Data for HIV/AIDS, when available, are displayed in Table IV, which appears quarterly.
 ††† Updated weekly from reports to the Influenza Division, National Center for Immunization and Respiratory Diseases. Since April 26, 2009, a total of 286 influenza-associated pediatric deaths associated with 2009 influenza A (H1N1) virus infection have been reported. Since August 30, 2009, a total of 279 influenza-associated pediatric deaths occurring during the 2009–10 influenza season have been reported. A total of 133 influenza-associated pediatric deaths occurring during the 2008–09 influenza season have been reported.
 ¶¶ The one measles case reported for the current week was imported.
 *** Data for meningococcal disease (all serogroups) are available in Table II.
 †††† CDC discontinued reporting of individual confirmed and probable cases of 2009 pandemic influenza A (H1N1) virus infections on July 24, 2009. During 2009, three cases of novel influenza A virus infections, unrelated to the 2009 pandemic influenza A (H1N1) virus, were reported to CDC. The one case of novel influenza A virus infection reported to CDC during 2010 was identified as swine influenza A (H3N2) virus and is unrelated to pandemic influenza A (H1N1) virus. Total case count for 2009 was provided by the Influenza Division, National Center for Immunization and Respiratory Diseases (NCIRD).
 ††††† In 2009, Q fever acute and chronic reporting categories were recognized as a result of revisions to the Q fever case definition. Prior to that time, case counts were not differentiated with respect to acute and chronic Q fever cases.
 ¶¶¶ No rubella cases were reported for the current week.
 ††††† Updated weekly from reports to the Division of Viral and Rickettsial Diseases, National Center for Zoonotic, Vector-Borne, and Enteric Diseases.
 ††††† Updated weekly from reports to the Division of STD Prevention, National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention.
 ††††† There was one case of viral hemorrhagic fever reported during week 12. The one case report was confirmed as lassa fever. See Table II for dengue hemorrhagic fever.

FIGURE I. Selected notifiable disease reports, United States, comparison of provisional 4-week totals August 21, 2010, with historical data

* Ratio of current 4-week total to mean of 15 4-week totals (from previous, comparable, and subsequent 4-week periods for the past 5 years). The point where the hatched area begins is based on the mean and two standard deviations of these 4-week totals.

C.N.M.I.: Commonwealth of Northern Mariana Islands.

U: Unavailable. —: No reported cases. N: Not reportable. NN: Not Nationally Notifiable. Cum: Cumulative year-to-date counts. Med: Median. Max: Maximum.

* Incidence data for reporting years 2009 and 2010 are provisional.

† Data for meningococcal disease, invasive caused by serogroups A, C, Y, and W-135; serogroup B; other serogroup; and unknown serogroup are available in Table I.

§ Contains data reported through the National Electronic Disease Surveillance System (NEDSS).

U: Unavailable. —: No reported cases. N: Not reportable. NN: Not Nationally Notifiable. Cum: Cumulative year-to-date counts. Med: Median. Max: Maximum.

* Incidence data for reporting years 2009 and 2010 are provisional.

[†] Illnesses with similar clinical presentation that result from Spotted fever group rickettsia infections are reported as Spotted fever rickettsioses. Rocky Mountain spotted fever (RMSF) caused by *Rickettsia rickettsii*, is the most common and well-known spotted fever.[§] Contains data reported through the National Electronic Disease Surveillance System (NEDSS).

C.N.M.I.: Commonwealth of Northern Mariana Islands.
 U: Unavailable. —: No reported cases. N: Not reportable. NN: Not Nationally Notifiable. Cum: Cumulative year-to-date counts. Med: Median. Max: Maximum.
 * Incidence data for reporting years 2009 and 2010 are provisional. Data for HIV/AIDS, AIDS, and TB, when available, are displayed in Table IV, which appears quarterly.
 † Updated weekly from reports to the Division of Vector-Borne Infectious Diseases, National Center for Zoonotic, Vector-Borne, and Enteric Diseases (ArboNET Surveillance). Data for California serogroup, eastern equine, Powassan, St. Louis, and western equine diseases are available in Table I.
 § Contains data reported through the National Electronic Disease Surveillance System (NEDSS).
 ¶ Not reportable in all states. Data from states where the condition is not reportable are excluded from this table, except starting in 2007 for the domestic arboviral diseases and influenza-associated pediatric mortality, and in 2003 for SARS-CoV. Reporting exceptions are available at <http://www.cdc.gov/ncphi/diss/nndss/phs/infdiss.htm>.

U: Unavailable. —: No reported cases.

* Mortality data in this table are voluntarily reported from 122 cities in the United States, most of which have populations of >100,000. A death is reported by the place of its occurrence and by the week that the death certificate was filed. Fetal deaths are not included.

† Pneumonia and influenza.

§ Because of changes in reporting methods in this Pennsylvania city, these numbers are partial counts for the current week. Complete counts will be available in 4 to 6 weeks.

¶ Total includes unknown ages.

The *Morbidity and Mortality Weekly Report (MMWR)* Series is prepared by the Centers for Disease Control and Prevention (CDC) and is available free of charge in electronic format. To receive an electronic copy each week, visit *MMWR*'s free subscription page at <http://www.cdc.gov/mmwr/mmwrsubscribe.html>. Paper copy subscriptions are available through the Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402; telephone 202-512-1800.

Data presented by the Notifiable Disease Data Team and 122 Cities Mortality Data Team in the weekly *MMWR* are provisional, based on weekly reports to CDC by state health departments. Address all inquiries about the *MMWR* Series, including material to be considered for publication, to Editor, *MMWR* Series, Mailstop E-90, CDC, 1600 Clifton Rd., N.E., Atlanta, GA 30333 or to mmwrq@cdc.gov.

All material in the *MMWR* Series is in the public domain and may be used and reprinted without permission; citation as to source, however, is appreciated.

Use of trade names and commercial sources is for identification only and does not imply endorsement by the U.S. Department of Health and Human Services.

References to non-CDC sites on the Internet are provided as a service to *MMWR* readers and do not constitute or imply endorsement of these organizations or their programs by CDC or the U.S. Department of Health and Human Services. CDC is not responsible for the content of these sites. URL addresses listed in *MMWR* were current as of the date of publication.
